

Evidence convergence is real but too diffuse to attribute to any gene

MOES was specified as four domains and two stages; three were excluded on their own evidence. The two that remain agree weakly about which genes matter most (~2x top-K overlap, global p 0.008–0.065) but no single gene survives testing across 10,387, so no hub list is reported.

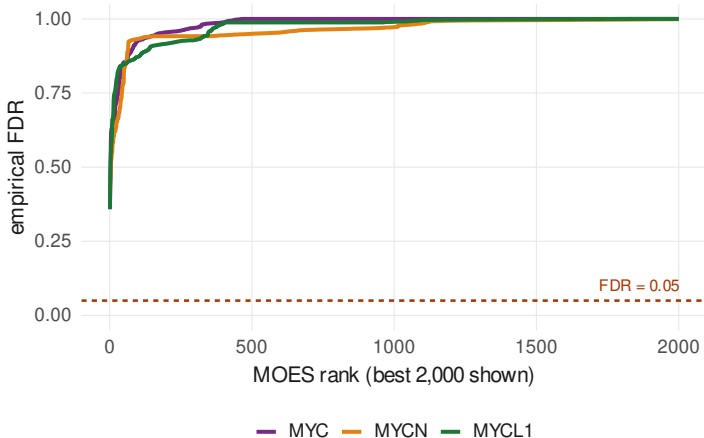

A · Weak convergence, above the permutation null

top-K overlap vs chance; grey = 95% null envelope
global p: MYC 0.019 · MYCN 0.008 · MYCL1 0.065

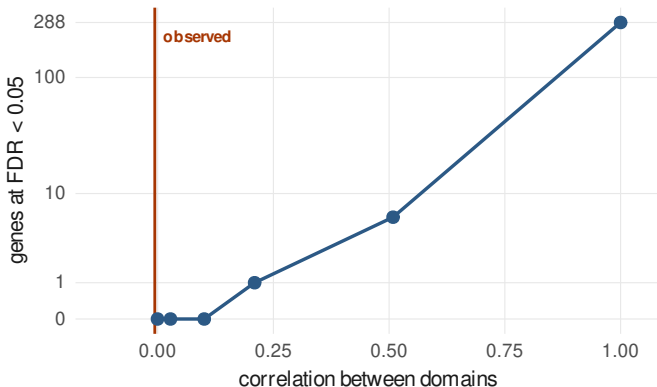

B · No gene comes close to significance

empirical FDR by MOES rank; best achieved is 0.358

C · The method finds signal when it is there

synthetic signal blended into the functional layer,
same FDR machinery; discoveries appear from $\rho \approx 0.2$

D · Paralogs look alike only via the shared layer

agreement between paralog rankings; the shared functional
layer pulls all three toward the same genes
